Automatic Microaneurysm Detection from Non-dilated Diabetic Retinopathy Retinal Images

Akara Sopharak, Bunyarit Uyyanonvara, Sarah Barman and Tom Williamson

ABSTRACT— Microaneurysms are the first clinical sign of diabetic retinopathy. The number of microaneurysms is used to indicate the severity of the disease. Early microaneurysm detection can help reduce the incidence of blindness. This paper investigates a set of optimally adjusted morphological operators used for microaneurysm detection on non-dilated pupil and low-contrast retinal images. The detected microaneurysms are validated by comparing with ophthalmologists’ hand-drawn ground-truth. As a result, the sensitivity, specificity, precision and accuracy were 81.61, 99.99, 63.76 and 99.98%, respectively.

INDEX TERMS— diabetic retinopathy, microaneurysms.

I. INTRODUCTION

Diabetic retinopathy (DR) is the most common cause of blindness in people of working age. The global prevalence of diabetes is expected to rise to 4.4% of the global population by 2030 [1]. An effective treatment to prevent vision loss is available, but diabetic retinopathy is asymptomatic until late in the disease process. The screening of diabetic patients for the development of diabetic retinopathy can reduce the risk of blindness by 50% [2]-[4]. With a large number of patients, the number of ophthalmologists is not sufficient to cope with all patients, especially in rural areas or if the workload of local ophthalmologists is substantial. Therefore, automated early detection could limit the severity of the disease and assist ophthalmologists in investigating and treating the disease more efficiently.

Microaneurysms (MA) are the earliest clinically localized characteristic of DR [5]. Their detection can be used to grade the DR stage as shown in Table I [6].

Most techniques mention earlier work on fluorescein angiographies or color images taken on patients with dilated pupils in which the MA and other retinal features are clearly visible. The examination time and effect on the patient could be reduced if the detection system could succeed on images taken from patients with non-dilated pupils. However, the quality of these images will be worse and it greatly affects the performance of those mentioned algorithms.

Automatic MA detection on images acquired without pupil dilation is investigated in this work with the aim of providing decision support in addition to reducing the workload of ophthalmologists.

In our previous work, we have presented methods for automatic exudate detection using a mathematical morphological technique, a FCM clustering technique, a combination of FCM and mathematical morphology, a naïve Bayesian classifier, a SVMs classifier and a nearest neighbor classifier [16]-[19]. To improve the overall ability of DR detection system, a MA detection method is proposed.

MA = microaneurysm, H = haemorrhage
II. Method

All digital retinal images taken of patients with non-dilated pupils were obtained from a KOWA-7 non-mydriatic retinal camera with a 45° field of view. The image size is 752 x 500 pixels with 24 bits per pixel. MAs are hard to detect because their contrast is very low and hardly visible and also difficult to distinguish from noise or pigmentation variations.

The proposed system has three main steps. The preprocessing step includes noise removal, contrast enhancement and shade correction. Candidate retinal features which may cause a false detection, i.e., exudates and vessels are detected in the second step. And the last step is MA detection by using a set of optimally adjusted mathematical morphology. The overall procedure of MA detection is shown in Fig. 1.

A. Preprocessing

A preprocessing step is needed to improve the image quality prior to the detection step. The green plane (\(g_b\)) of the original RGB color image was used as red lesions have the highest contrast with the background in this color plane [20]. A median filtering operation was applied on \(g_b\) to reduce noise before a Contrast Limited Adaptive Histogram Equalization was applied for contrast enhancement. A dark region (including noise and MAs) may dominate after contrast enhancement. To account for this a shade correction algorithm was applied to the green band in order to remove slow background variation due to non-uniform illumination. The original image in the RGB plane, the green band image, the green band image after removal of noise and contrast enhancement, and the shade corrected image (\(f_{sc}\)) are shown in Fig. 2 (a) through Fig. 2 (d).

B. Exudate Detection

MA detection is our main purpose, however we have to remove bright lesions such as exudates prior to the process because when they lie close together, small islands are formed between them and they can be wrongly detected as MAs. Mathematical morphological methods (proposed in our previous work [16]) was used due to its computationally low cost. Examples of exudate detection results overlaid on the original image are shown in Fig. 3.

C. Vessel Detection

Vessels are another element in the image that needs to be removed prior the MA detection since MA and vessels both appear in a reddish color and MAs cannot occur on vessels.

To detect vessels, two intermediate images are generated. The first image is obtained using a closing operator (\(\phi\)) on image \(f_{sc}\) to eliminate the details from the image. A second image is obtained by filled-in small black dots on \(f_{sc}\) with diameters smaller than size of MA in order to remove small red objects and fill holes in the vessel. The diameter of a MA lies between 10 and 100 µm, but it always smaller then a diameter \(λ < 125 \mu m\) [6]. In our image set of size 752 x 500 pixels, the size of a MA is about 10 pixels. Vessel candidate areas are obtained by the difference between the first image and the second image from the previous step. The closing image and filled in image are shown in Fig. 4 (a) and Fig. 4 (b).

\[
\begin{align*}
\text{Result image} &= \text{object which} \quad \text{is} \quad \text{the} \quad \text{morphological} \quad \text{structuring} \quad \text{element}.
\end{align*}
\]

where \(B_i \) is the morphological structuring element.

The candidate vessels were then thresholded at grey level \(\alpha_i\) as in (2). Let \(T = \{t_{\min},...,t_{\max}\}\) be an ordered set of grey levels, we have

\[
\begin{align*}
\text{Result image} &= \text{object which} \quad \text{is} \quad \text{the} \quad \text{morphological} \quad \text{structuring} \quad \text{element}.
\end{align*}
\]

As a result shown in Fig. 4 (c), there are some small isolated objects left. The objects which have size smaller than 10 pixels (size of MA, as mentioned above) are then removed from \(f_{vesselT}\). The result is shown in Fig. 4 (d).

D. Microaneurysm Detection

Retinal MAs are focal dilatations of retinal capillaries. They are discrete, localized saccular distensions of the weakened capillary walls and appear as small round dark red dots on the retinal surface.

According to the medical definition of MA [5], [6], it is a reddish, circular pattern with a diameter \(\lambda < 125 \mu m\). We aim to find an MA by its diameter and isolated connected red
pixels with a constant intensity value, and whose external boundary pixels all have a higher value; in the green plane of a RGB image.

A preprocessed retinal image was used as preliminary image for MA detection. The extended-minima transform [21] is applied to the $f_{sc}$ image. This transformation is a thresholding technique that brings most of the valleys to zero. The extended minima transform on the $f_{sc}$ image with threshold value $\alpha_2$ is shown in (3).

$$f_E = EM(f_{sc}, \alpha_2)$$

(3)

where $f_E$ is the output image.

The selection of threshold is very important where the higher value of $\alpha_2$ will lower the number of regions and a lower value of $\alpha_2$ will raise the number of regions. The result is shown in Fig. 4 (e). The previous detected exudates and vessels were removed from the resulting image. The result is shown in Fig. 4 (f).

$$f_{VE\_removed} = f_E - f_{vessel} - f_{es}$$

(4)

where $f_{es}$ is the exudate detected image.

Then the objects with a size smaller or equal to 10 pixels are selected and classified as MAs. The result is shown in Fig. 4 (g).

There are parameters used in this experiment. They are, namely, the size of structuring element ($B_1$) used for the closing operation, threshold values ($\alpha_1$ and $\alpha_2$). $\alpha_1$ was calculated automatically using the Otsu algorithm. $B_1$ and $\alpha_2$ were varied and tested in order to assess the algorithm performance in an experiment. Each parameter was varied as follows:

$$B_1 \in \{9, 10, 11, 12\}$$

$$\alpha_2 \in \{0.01, 0.03, 0.05, 0.07\}$$

All parameters in this proposed method are set using the values that gave highest sensitivity and specificity in the previous experiment. The experiment showed that the value of $B_1=10$ and $\alpha_2 = 0.05$ gave a good balance between the number of detected MAs and the number of detected spurious objects.

III. RESULTS

Data sets of 45 non-dilated retinal images are tested. Detected MAs are compared with the ophthalmologists’ hand-drawn ground-truth images for verification. Sensitivity is the percentage of the actual MA pixels that are detected, and specificity is the percentage of non-MA pixels that are correctly classified as non-MA pixels. Precision is the percentage of detected pixels that are actually MAs. Accuracy is the overall per-pixel success rate of the classifier.

Sensitivity, specificity, precision and accuracy in this experiment are 81.61, 99.99, 63.76 and 99.98%, respectively. The numbers of MAs are also counted for automated grading of the severity of the DR. Example resulting images of MA detection are shown in Fig. 5.

IV. CONCLUSION AND DISCUSSION

Our work concentrates on microaneurysm detection from diabetic retinopathy patient’s non-dilated pupil digital images. It is an extension to our previously proposed automated DR screening system. The system intends to help the ophthalmologists in the diabetic retinopathy screening process to detect symptoms faster and more easily. The algorithm could detect MAs on very poor quality images. Although further development of this algorithm is still required, the results are satisfying. The outcome is quite successful with sensitivity and specificity of 81.61% and 99.99%, respectively. The system also provided ophthalmologists with the number of MAs for grading the DR stage. In order to apply to a clinical application, the proposed method will be combined with an exudate detection system.
