Abstract—We propose a change point detection algorithm for a sequence of graphs. Our algorithm focuses on the change of the structure of densely connected subgraphs (community structure) rather than the change of the link weights. In contrast to the traditional approaches, the algorithm can identify the structure change more sensitively. Experiments with a synthetic data and a real-world data of graphs showed that our algorithm can accurately locate the changed subgraph compared with some of the state-of-the-art algorithms.

Index Terms—Anomaly detection, Evolution network, Martingale, Spectral clustering

I. INTRODUCTION

Graphs naturally arise in the current circumstance as seen in computer networks, World Wide Web, climate networks, social networks and biological networks. Accordingly anomaly detection of graphs has been gathering a great deal of attentions. For example, in the network intrusion detection, we want to find malicious messages (e.g spammers, port scanners) among many ordinary messages, and in the climate networks, we want to find anomalous phenomena (e.g heavy rain, storm) from signals obtained by several sensors.

Typical networks have dynamic nature and often keep growing or shrinking with time. Such dynamics should be taken into consideration for the design of anomaly detectors. In human/social networks represented by graphs with weighted undirected/directed links, a community that is a subgraph whose members are connected strongly to each other is a key factor to specify the characteristics of the graphs. In the view point of community, we can divide anomaly into that in the community structure and that in the community strength/activity.

A graph may change its communities in the member and/or in the way of connections, while another graph may strengthen or the connections among community members may be weaken. One example of the latter case is a local computer network where many messages have been exchanged regularly. In this example, a server and clients may make a community. Once a client is hacked, it may behave differently and send irregular messages to specific computers. Such anomaly would be detected as the change of link strength. Another example is a scientific network, where a node represents a scientist and a link represents the co-author relationship among scientists. A community in this network is seen as a group of scientists sharing similar interests. The community may grow due to some boom of a specific subject and shrink due to maturity of the field. Such changes could be observed both in the community activity and community structure.

In this paper, we proposed an anomaly detector which has following key properties.

- It concentrates on communities
- It detects mainly the change of community structure.
- It can work online.

We put the following assumptions on the input data: (1) no domain knowledge is available on the nature of network. (2) data arrives sequentially, (3) all links are not directed, (4) there exist some communities, that is subsets of dense connections.

The rest of papers are organized as follows. We briefly review some related works, in Section II. In Section III, our terminology and assumptions are presented. In Section IV, we describe the details of the proposed method. The experimental results are presented in Section V. We discussed the characteristics of our algorithm in section VI and summarized this paper in Section VII.

II. RELATED WORK

In a static network, one goal is to find anomalous nodes or links which can be regarded as topological outliers. There have been proposed dozens of rarity/affinity measures for such outliers such as Random Work Similarity [1], [2]. Information theoretic measure [3]–[5], density measure [6] and so on. We also use an affinity measure, but it finds transitions in the dynamics of graph rather than topologically rare nodes or links.

In a dynamic network, we concentrate on finding the change points on the dynamics. Specifically, we consider that a change happens when the densely connected nodes is separated, or sparsely connected nodes have dense connections. These changes can be found on the basis of the community, a group of nodes with densely connections. GraphScope [7] finds communities in the unweighted graph and detect when these communities changed. However, it cannot be applied to the weighted graph. Spectral based anomaly detection [8]–[11] deals with the weighted graphs and detects the time point when the densely connected subgraphs change. These methods identify dense connections thorough spectrum information of a matrix representing a graph. However, these approaches only monitor the changes on the dense subgraphs.

Our algorithm also makes use of the spectrum to identify community structure, but it also monitors the changes on the sparse connections as well as the dense connections.

III. PREPARATION

A. Notation

Bold letters always denote random matrices. Superscript in parentheses denote time and subscripts i, j denote a row and a column of a matrix.

A graph \( G \) consists of a set \( V \) of nodes and a set \( E \) of links. Furthermore, each link has a weight \( w \in [0, \infty) \) representing the strength of connection. The matrix operator \( \text{diag}() \) and \( \text{off-diag}() \) decompose a matrix into the diagonal part and the non-diagonal part respectively.

A symmetric matrix \( X \) can be decomposed into \( X = \Gamma \Lambda \Gamma' \), where \( \Gamma \) is an orthonormal matrix with eigenvectors of \( X \) in columns and \( \Lambda \) is a diagonal matrix with corresponding real value eigenvalues. The column vectors of \( \Gamma \) are sorted in the descending order of its corresponding eigenvalues.

B. Community

Communities can be analyzed by the spectrum of a matrix representing a graph [12], [13]. To make clear the meaning of spectrum, let us consider an adjacency matrix \( X \) shown in Fig 1. Let us decompose \( X \) into \( X = \Gamma \Lambda \Gamma' \) where \( \Gamma \) is a matrix whose column is an eigenvector of \( X \) and \( \Lambda \) is a diagonal matrix whose diagonal elements are the real value eigenvalues. All of eigenvectors of \( \Gamma \) and the diagonal elements of \( \Lambda \) are shown in Table I. Here it is noted that \( \Gamma_1 \) and \( \Gamma_2 \) correspond two communities \( C_1 = \{v_1, v_2, v_3\} \) and \( C_2 = \{v_4, v_5, v_6\} \), respectively. The eigenvalues represent the strength of connectivity in the communities. The community \( C_1 \) has the strongest connectivity and \( C_2 \) follows.

For a graph consists of \( l \) dense subgraphs, Peron Frobenius Theorem [14] guarantees that there exist \( l \) positive eigenvalues expressing the strength of connectivity corresponding to the \( l \) communities and its corresponding eigenvector has large elements in its participating nodes. Such community is known as eigencenter [13] and the property of a graph can be separated into community structure and community activity.

DEFINITION (Community structure and activity)

For a graph \( G \) expressed by an adjacency matrix \( X \)

with its own decomposition \( X = \Gamma \Lambda \Gamma' \), we call the positive eigenvalues of \( \Lambda \) the “community activity” and its corresponding eigenvector of \( \Gamma \) the “community structure”.

When the number \( l \) of communities is known, we can find the largest \( l \) eigenvalues and eigenvectors as \( X \simeq \Gamma_1 \Lambda_1 \Gamma_1' \).

IV. PROPOSED METHOD

In this section, we present our algorithm to detect the changes in community structures \( \Gamma \). Our basic assumption is that the community structure is almost invariant over time, in other words, dense/sparse connections would be unchanged even though their weights of links may change to some extent. In the following, we formalize the model of graph evolutions and introduce our algorithm.

A. Model

Let us consider a sequence of random graphs \( G = \{G^{(1)}, G^{(2)}, \ldots, G^{(t)}\} \) represented by adjacency matrices \( X = \{X^{(1)}, X^{(2)}, \ldots, X^{(T)}\} \), \( X \in \mathbb{R}^{n \times n}, t = 1, 2, 3, \ldots \)

We assume that, as a normal state, the \( X^{(t)} \) is generated independently from the following model:

\[
X^{(t)} = \Gamma (\Lambda + N^{(t)}) \Gamma', \quad t = 1, 2, \ldots, (1)
\]

where the structure \( \Gamma \) is assumed not to change as well as activity \( \Lambda \), while \( N^{(t)} \) can change as a random noise (not always diagonal) matrix with mean zero matrix.

The expectation of matrix \( X^{(t)} \) is given by

\[
E X^{(t)} = \Gamma \Lambda \Gamma' + \Gamma (E N^{(t)}) \Gamma' = \Gamma \Lambda \Gamma'.
\]

Therefore, assuming ergodicity of \( X^{(t)} \) for a period \( t \in [1, T] \), we estimate \( E X^{(t)} \) as a sample mean as

\[
\bar{X} = \frac{1}{T} \sum_{t=1}^{T} X^{(t)} \simeq \Gamma (\Lambda) \Gamma'. \quad (2)
\]

Then, we estimate \( \Gamma \) and \( \Lambda \) by decomposition of \( \bar{X} \). By choosing the principle \( l \) components of \( \Gamma \) and \( \Lambda \), we construct \( \Gamma_l \) and \( \Lambda_l \) as well. When the graph seems to be generated from this model, we regards the graph is in normal state, but if it does not, we consider the data is in abnormal state. In the following, we quantify the deviation of the graph from this model and descriminate the normal and anomaly deviations.

B. Anomaly Measure

Suppose that the model \( (\Gamma, \Lambda) \) changes to \( (\bar{\Gamma}, \bar{\Lambda}) \) at time \( t_0 \). By monitoring the amount of fluctuation of corresponding community structure \( \Gamma \), this change is detected. In the following, we assume that \( \Gamma \) and \( \Lambda \) are already estimated from the past sequence by Eq. (2). We decompose \( X^{(t)} \) by multiplying \( \Gamma \) and \( \Gamma' \) in both sides as

\[
X^{(t)} = \Gamma Y^{(t)} \Gamma'.
\]

At this time, \( Y^{(t)} \) is not diagonal in general. Therefore, we separate the components into the diagonal part and the non-diagonal part as

\[
X^{(t)} = \Gamma (\text{diag} Y^{(t)}) \Gamma' + \Gamma (\text{off-diag} Y^{(t)}) \Gamma'. \quad (4)
\]
Similarly, we separate the Eq. (1) as
\[
X^{(t)} = \Gamma(A + N^{(t)})\Gamma' = \Gamma(A + \text{diag}(N^{(t)}))\Gamma' + \Gamma(\text{off-diag}(N^{(t)}))\Gamma'. \quad (5)
\]
Comparing Eq. (4) and Eq. (5), we can see that diag\((Y^{(t)} - \Lambda)\) shows the regular fluctuation within communities, by noise \(N^{(t)}\) and off-diag\(Y^{(t)}\) shows the fluctuation between communities. Both amounts are supposed to be small if the model does not change. However, if the structure changes from \(I\) to \(\Gamma\), the amount of fluctuation caused by the change would be put on the second term of Eq. (4). Indeed, if the model is unchanged, that is, if Eq. (4) and Eq (5) are equal,
\[
E\left(\text{off-diag}(Y^{(t)})\right) = E\left(\text{off-diag}(N^{(t)})\right) = O. \quad (6)
\]
Therefore we consider off-diag\(Y^{(t)}\) as the fluctuation in the community structure. Let us denote an anomaly score of the graph at time \(t\) as \(a^{(t)}\), which is defined as
\[
a^{(t)} = ||\text{off-diag}(Y^{(t)})||_F = \text{Tr}\left(\left(\text{off-diag}(Y^{(t)})\right)^T\left(\text{off-diag}(Y^{(t)})\right)\right). \quad (7)
\]
where \(||\cdot||_F\) is the frobenius norm. The anomaly score \(a^{(t)}\) measures the amount of fluctuation in community structure and a high score implies that the model might be changed.

C. Martingale Test

From the sequence of anomaly scores \(a^{(t)}\), \(t = 1, 2, \ldots\), we would like to find the time when the community structure is changed. Because \(N^{(t)}\), \(t = 1, 2, \ldots\) are generated from a stationary distribution, \(Y^{(t)}\) and \(a^{(t)}\), \(t = 1, 2, \ldots\) are also expected to have stationary properly as well. In other words, if the distribution of \(a^{(t)}\) has changed, we may consider the model changed.

To evaluate the changes in the distribution of \(a^{(t)}\), we employ a non-parameteric statistical test based on Randomized Power Martingale (RPM) [15]. Given a sequence of anomaly scores \(a^{(1)}, a^{(2)} ,\ldots, a^{(t)}\), the RPM is defined as
\[
M^{(t)} = \prod_{k=1}^{t} (\epsilon \hat{p}^{(t-1)}_k), \quad (8)
\]
where \(\epsilon \in (0, 1)\) and the \(\hat{p}_k\) is given by the \(\hat{p}\)-value function
\[
\hat{p}_k = \sum_{i=k}^{\infty} I\{a^{(i)} > a^{(k)}\} + \sum_{i=1}^{k} u_i I\{a^{(i)} = a^{(k)}\} \quad (9)
\]
where \(1\{S\}\) becomes 1 in case that \(S\) is true otherwise 0 and \(u_i\) is a random variable drawn from a uniform distribution over \([0, 1]\). Here it is easily confirmed that the \(\hat{p}\) value are distributed uniformly over \([0, 1]\). Therefore the conditional expectation of \(M^{(t)}\) with respect to the past \(\hat{p}\)-values \(\hat{p}_1, \hat{p}_2, \ldots, \hat{p}_t\) is given by
\[
E\left[M^{(t)}|\hat{p}_1, \hat{p}_2, \ldots, \hat{p}_t\right] = M^{(t-1)} \int_0^{1} \epsilon \hat{p}^{(t-1)} d = M^{(t-1)}. \quad (10)
\]
This property “the expectation of the next value is the same as the current value” is called martingale and it satisfies Doob’s Maximal Inequality [16, 17]:
\[
P\left(\sup_{0 \leq s \leq t} M^{(s)} \geq 1/\delta\right) \leq \delta, \quad (11)
\]
where \(\delta \in (0, 1]\) is a significance level. From this inequality, we see that a change happens with probability \(1 - \delta\) when \(M^{(t)}\) exceeds \(1/\delta\). The parameter \(\epsilon\) takes responsible for determining the sensitivity for the changes. Specifically, the small \(\epsilon\) increases sensitiveness for the changes, but it causes false alarms. According to [15], it is appropriate to set \(\epsilon\) in \([0, 1]\).

V. Experiment

We have conducted two experiments using one synthetic dataset and one real-world data. We compared the proposed method with other spectral approaches: EigenSpace [9], EigenCompress [11]. In EigenSpace, the most strongly connected subgraph is assumed to be invariant over time. EigenCompress, on the other hands, focuses on the activity of communities, thus detect the change of eigenvalues. These characteristics are summarized in Table II.

A. Synthetic data

In this experiment, we aimed to confirm that the changes of community structures are correctly detected by our algorithm. The basic structure of the graphs used in this experiment is shown in Fig 2. This basic graph consists of two communities \(C_A = \{v_1, v_2, v_3, v_4\}\) and \(C_B = \{v_5, v_6, v_7, v_8\}\). We gave a random uniform fluctuation \(u \in [-1, 1]\) to the

weight of link \( w_{i,j} \) between nodes \( v_i \) and \( v_j \) as

\[
 w_{i,j} = \begin{cases} 
\mu_{AA} + 0.2u & \text{if } (v_i, v_j) \in C_A \\
\mu_{BB} + 0.2u & \text{if } (v_i, v_j) \in C_B \\
\mu_{AB} + 0.2u & \text{if } (v_i, v_j) \in C_B 
\end{cases} 
\tag{12} 
\]

where \( \mu_{AA}, \mu_{BB} \) and \( \mu_{AB} \) are basic weights of within communities and between communities. A sequence consists of 200 graphs was generated according to this model. We tested 4 scenarios as shown in Fig (3), in which a change occurs at time \( t_0 = 100 \) and the parameters were changed to \( (\mu_{AA}, \mu_{BB}, \mu_{AB}) \) as shown in Table III. The scenarios 1, 2 and 3 change the weights of intra-communities and the scenario 4 changes in the weights of inter-communities. We constructed a dataset consists of 100 sequences generated by unchanged model (12) and 100 sequences including a change according to one of above scenarios and tested whether the algorithm distinguishes changed cases and unchanged cases correctly or not.

We measured the area under curve (AUC) of the graph as the plane of which horizontal axis is the false alarm rate and vertical axis is recall value (Fig. 4). The AUC was calculated by the trapezoid integration. While we gradually changed the value of parameters of the algorithms, we measured the false alarm rate and recall. For the EigenSpace and the proposed method, the significance level \( \delta \) was changed. For EigenCompress, the threshold value for the anomaly scores was changed since this method does not have any parameter to determine the significance level.

The other parameters were set so as to achieve the highest average AUCs over the 4 scenarios. For EigenSpace, the learning parameter \( \beta = 0.03 \) and the window size \( w = 30 \). The number of eigenvalues monitored by EigenCompress was 3. For our algorithm, we set \( l = 2 \) and \( \epsilon = 0.95 \).

The AUCs are summarized in Fig 5 (a). As expected from their characteristics, Eigenspace succeeded in detecting only the change of the structure of the most densely connected community, that is, the change of scenario 3 (the strongest community moves from \( C_A \) to \( C_B \)), while EigenCompress succeeded in detecting the change of activities of both communities in scenarios 1, 2 and 3. The reason why the proposed algorithm aiming the detection of the changes of the community structure succeeded in detection of the inter-community changes is that the activity change also derives the structure change. For example, in scenario 1, the right community relatively vanished after strengthening of the left community.

Next, we examined the mean delay time (MDT) of these algorithms. To unify the sensitivity of detectors, we set the value of parameters of algorithms as follows. For EigenSpace and the proposed method, we set the significance level to 0.05. For EigenCompress, the threshold values is determined such that the ratio of anomaly scores over the threshold is 0.05.

Fig 5 (b) shows the result of MDT. We observe that the proposed algorithm has the longest delay in all scenarios. This is because the the martingale \( M(t) \) exceeds the boundary (11) after observing several high anomay scores, while other methods issues alarm once one high anomaly score is observed.

B. Enron email dataset

This dataset [18] consists of the email records in Enron Inc. observed during January 1999 to Jury 2002. A node represents an individual employee and an edge represents the email exchange relationship. The weight of a link represents...

The number of emails exchanged between the corresponding two employees. In this graph, the most densely connected subgraph corresponds to an executive committee exchanging many emails to run the company. The other subgraphs consist of communications between executives and employees in corresponding sections.

The special events happened during this period are summarized in Table IV and the number of emails in each day is shown in Fig 6 (a). We see that the number of emails started increasing after the event #1 according to the company growth. Before the event #5, it reached its peak since the executives exchanged many emails to prepare the risk of possible bankrupt.

We examined whether our algorithm detects changes related to these events. We observed that there were more than 3 positive eigenvalues over this period, and thus we set $l = 3$. It might be hard to locate the cause of changes after a long delay and therefore we set $\delta = 0.05$ and $\epsilon = 0.9$ in order to detect the changes quickly.

The martingale values were plotted in Fig 6 (b). The four of changing time points were detected : (A) 06 Jul 1999, (B) 07 Mar 2000, (C) 13 Jan 2001 and (D) 30 May 2001. Only #4 event is detected as a change. To interpret the result, we have to consider again what kind of changes are detected by the proposed method. As seen in Fig 6 (b), our change detector waits until certain amount of evidence of strangeness is gathered, so that it does not detect an abrupt change but a gradual change to some extent. In this sense, our detector might have detected changing points of organizational life cycle: birth, growth, maturity, decline and death. Under this explanations, the period before (A) corresponds to “birth”, the period (A)-(B) to “growth”, the period (B)-(C) to “maturity”, the period (C)-(D) “decline” and the period (D)- to “death”. These interpretation may be supported by the events #1-#5 happened in the corresponding period, e.g the highest stock price was marked (#2) just after the end of growth period.

To examine the validity of those interpretations, we visualized the graphs corresponding to these periods. Fig 7 shows the time series of subgraphs consists of the nodes corresponding to 3 strongest communities. Although it might be a little intentionnal, Fig 7 (a) -Fig 7 (d) look as showing (a) the CEO intensively listens to the opinion of external members and two sections worked for lunching “EnronOnline”, (b) 4 sections are organized, (c) new employees participated and also some employees moved their sections, and (d) intensive discussion is made among vice presidents.

We also have to notice that the amount of emails does not directly affected to the structure of communities. It mainly impacts on the activity (the weight of links of communities). In this sense, the change of the amount of emails shown in Fig 6 (a) is not directly related to the results. Therefore, one possible explanation about why our detector fails to detect the events is because the communities of exchanging many emails did not change the members but increased the activity only in accord with the growth to maturity period.
VI. DISCUSSION

A. Detectable changes

The proposed algorithm detects not only the change of community structure, but also the change of community activity. This is reasonable in some sense. Strictly speaking, the community structure and community activity cannot be separated so clearly because the structure may change due to the heavily weakened links or strengthened links.

Our algorithm is slow to report a change compared to the other methods. The competitors are designed to detect the abrupt changes as it happens, but our algorithm detects changes after gathering a necessary amount of evidence. Therefore, it takes longer delay and thus the temporal change might be missed. It may be possible to use our algorithm to report a past change later, which might be useful in some applications.

B. Computational Complexity

The eigen decomposition of $X$ costs $O(n^2)$ and the multiplication of $\Gamma$ to compute off-diag $Y$ costs $O(n^3)$. The anomaly score is computed at cost of $O(n^2)$ and therefore the total cost of computing anomaly score is $O(l^2 + n^2 + n^3) = O(n^3)$. If we employ a heap-sort algorithm for ordering anomaly scores, $\tilde{p}$ value in Eq. (9) can be computed at cost of $O(T \log T)$ where $T$ is the number of data in a segment. Since $n$ is very large in general compared to $T$, the total computation cost becomes $O(l^2 + T \log T) \simeq O(l^3)$. However, it can be efficiently reduced to $O(l^2)$ by employing the incremental spectrum updating techniques [19], [20] for the eigen decomposition of $X$.

C. Laplacian Matrix and Modularity Matrix

In this paper, we focused on the changes of the communities on the basis of the eigenvectors of an adjacency matrix. In this case, the community is a group of nodes with dense connections. Such a property “an eigenvector of a matrix expresses affinities among nodes” can be also dealt with the Laplacian Matrix [12], [21] and the Modularity Matrix [22], [23]. In the future, we will compare these with the proposed method.

VII. CONCLUSION

In this paper, we have proposed an anomaly detection algorithm for evolutionary networks. We have assumed that a community is a dense subgraph and the invariant of the structure of a community can be confirmed by the unchanged eigenvectors. The traditional approaches monitor mainly the strongest community, while our approach monitors many principle communities. This algorithm also outperforms the others in detection of a change of activity between different communities.

We compared our algorithm with two state-of-the-art algorithms and confirmed its effectiveness. On the other hands, its response was three times later than the other methods. The results on the email communication showed that our algorithm detected changes longer or shorter before the critical event happens.

Further analysis is needed to reduce the delay and the property of other matrix would be more cleared by comparison with our algorithm.

REFERENCES
